Keywords: Apartment house Main construction materials Environmental load (CO₂) Evaluation system

ABSTRACT

The purpose of this study is to develop a simple method to assess the amount of carbon dioxide (CO₂) emitted during the production of construction materials used in the construction of a standard Korean apartment house. This study is part of a wider effort to develop a system for evaluating the environmental load of construction during architectural planning and basic design phases.

We formulated models of a standard Korean apartment house and a super high-rise apartment house, based on five reference floor plans for "green homes" provided by the Korean government. We identified major construction materials that account for over 80% of the CO_2 emission that occurs during construction and built a database to evaluate the environmental loads of these materials according to house types described in terms of area, block type, combination of living units, or number of floors. We used the information in this database to develop technology to assess the amounts of CO_2 that are emitted during the production of construction materials used to build residential apartment houses in Korea.

1. Introduction

It is probable that a post-Kyoto protocol, or convention on climate change that applies to the widest scope of society will need to be formulated in order to combat the accelerating pace of global warming. Numerous efforts have already been made to reduce greenhouse gases according to the Kyoto Protocol adopted in 1997 by the United Nations Framework Convention on Climate Change (UNFCCC). The most pressing issue of the post-Kyoto regime, however, is that the countries most often blamed for high greenhouse gas emissions were excluded from the group of Annex I countries. As a result, serious attempts to adopt a farther-reaching global convention on climate change, including both industrialized and developing countries after 2013, have been made [1,2].

Since an international bond of sympathy has developed and the post-Kyoto regime has approached the Korean government presenting both opportunities and threats, the Korean business sector has started to make efforts to respond to the problem of climate change. For example, one large company in Korea recently announced a "Green Management" scheme, voluntarily set a goal of reducing greenhouse gases, and proclaimed that it will make a large-scale investment in facilities to reduce carbon and develop environment-friendly technologies. The amount of greenhouse gas emission in Korea, however, has continued to increase, and if Korea fails to address these problems it is likely that Korean businesses will lose opportunities to enhance Korea's export strength and to create new growth engines [3–5].

Until recently, Korean construction companies have placed little priority on decreasing environmental load (CO_2) . However, environmental concerns have led the Korean construction community to develop environment-friendly element technologies aimed at reducing carbon dioxide (CO_2) emissions that occur during the construction of new buildings. Such technologies must be accompanied by the development of a system for evaluating the environmental load (CO_2) of newly-constructed buildings, but few active efforts to develop such environmental load evaluation programs have been made [6-9].

We developed a method to evaluate the lifetime environmental load of a newly-constructed building by using a minimum amount of data derived only during the architectural planning and basic design stages, that does not require data regarding the actual construction of the building or calculation of energy consumption. We then identified the main construction materials responsible for CO_2 emission during the construction of apartment houses, and tested our new method, which easily evaluated the amount of CO_2 emitted during the production of materials used for construction [10,11].

2. Standard apartment house

2.1. Selection of standard apartment house

A standard apartment house consists of certain combinations of living units, number of floors, structure and strength. Five standard apartment house models were described in the Guideline for Evaluating Design and Performance of Green Houses subject to the Criteria to Build Green Houses and their Performance, announced in October 2009 by the Ministry of Land Transport and Maritime Affairs of Korea. The "standard apartment house" referred to in this study is a reference house designed for the evaluation of environmental load ($\rm CO_2$). Based on five floor plans designated as "Green Home" reference plans by the Korean government, we designated floor plans for apartment houses of 15–20 stories as standard apartment house models (hereafter referred to as "general standard apartment houses"), as well as a standard model for a super high-rise (60-story) apartment house (hereafter referred to as "super high-rise standard apartment house") [12,13].

The Guideline for Evaluating Design and Performance of Green Houses uses reference designs for baseline evaluations, and therefore the standard floor plans used in this study were designed for use in comparisons of energy savings and $\rm CO_2$ reduction. The Guideline describes typical floor plans (36–125 m²) for Korean apartment houses, including the areas of their walls, windows, doors, floors, roofs, and other parts.

2.2. General standard apartment house

The general standard apartment houses were selected on the bases of area, combination of living units, number of floors, structure, strength, and other factors. The lettable areas of the apartment houses were divided into five groups by size: $36~\text{m}^2$, $46~\text{m}^2$, $59~\text{m}^2$, $84~\text{m}^2$, and $125~\text{m}^2$. The block arrangements of buildings are divided into flat, tower, block, and terrace house types, and of these, the flat and tower types are the most common. The flat type denotes a floor plan that forms a straight line while the tower type describes a floor plan in which the ratio of the short side to the long side is 1:2 or less.

In this study, the living units were arranged in either two-unit or four-unit combinations, because these are the two most prevalent types of block arrangement in Korea. Therefore, the general standard apartments were classified as two-unit combined flat type, four-unit combined flat type, or four-unit combined tower type. Figs. 1 and 2 show the five floor plans, block arrangements, and combinations of living units of the general standard apartment houses considered in this study. Ceiling height was set at 2.9 m for all floor plans after consideration of air supply and ventilation systems. The number of floors was limited to 15- to 20-stories, as these are the most common building heights in Korea. The structures of all buildings incorporated wall column type reinforced concrete, with the strength of the concrete set to 24 MPa for all floors for practical reasons. Table 1 outlines the specifications of the general standard apartment house models considered in this study.

2.3. Super high-rise standard apartment house

A model of a super high-rise standard apartment house was formulated using the criteria of area, combination of living units, number of floors, structure, strength, and other factors. The lettable areas of the super high-rise standard apartment houses were divided into three groups by size: $118 \, \mathrm{m}^2$, $121 \, \mathrm{m}^2$, and $178 \, \mathrm{m}^2$. The areas differed according to floor: the third to the 28th floors incorporated four-unit combinations of $118 \, \mathrm{m}^2$ and two-unit combinations of $121 \, \mathrm{m}^2$, with six-unit combinations in

Table 1Constitution of general standard apartment houses.

Constitution	Description
Lettable area	36 m ² , 46 m ² , 59 m ² ,
	$84 \mathrm{m}^2$, $125 \mathrm{m}^2$
Block arrangement	Flat type: the floor plan is a
	straight line.
	Tower type: the ratio of the
	short side to the long side of the
	plan is 1:2 or less.
Combination of living units	Flat type: one combination (two-unit
	combined flat type)
	Tower type: two combinations (four-unit
	combined flat type, four-unit
	combined tower type)
Height of ceiling	2.9 m: air supply and ventilation
	systems are taken into account.
Number of floors	15–20 floors
Structure	Wall-column structure of reinforced
	concrete
Concrete strength	24 MPa for all floors

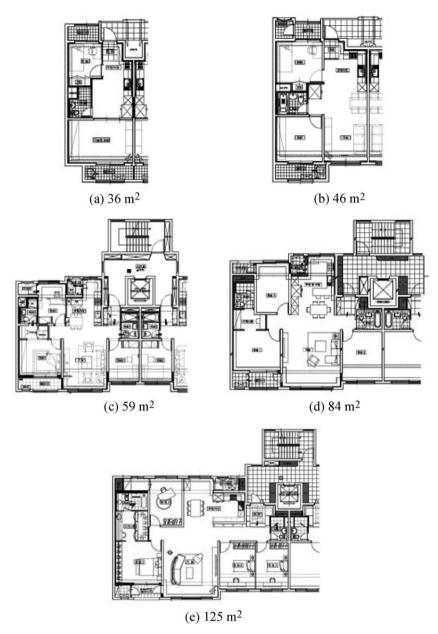

Fig. 1. Five floor plans of general standard apartment houses.

total; the 30th to the 60th floors incorporated four-unit combinations of $178 \, \text{m}^2$. Fig. 3 shows the block arrangements and combinations of living units of the super high-rise standard apartment houses considered in this study.

The tower type block arrangement was used for the super highrise standard apartment houses considered in this study because it is the most common arrangement found in tall Korean buildings. As for the combination of living units, two floor plans were combined for the third to 28th floors, while one floor plan was used for the 30th to 60th floors. The ceiling height was set at 2.9 m after consideration of the air supply and ventilation systems in construction. The building incorporated a wall column structure with a core wall of reinforced concrete, and the strength of the concrete varied according to the zoning per floor. The strength of the core wall was 50 MPa from the first to 45th floors and 30 MPa from the 46th to the 60th floors. The strength of the structures was 40 MPa from the first to the 45th floors and 30 MPa from the 46th to the 60th floors. The specifications of the super high-rise standard apartment houses considered in this study are summarized in Table 2.

3. Main construction materials

3.1. Overview

Based on other research that analyzes the specifications of construction for an apartment house built in May 2004, the CO_2 emissions were evaluated per construction process for the purpose of selecting the main construction materials that emit CO_2 . As a result, the amount of CO_2 emission by the production of construction materials per process was highest in the process of building work (352.36 kg- CO_2/m^2), followed by the processes of facility work (49.68 kg- CO_2/m^2) and earth work (11.15 kg- CO_2/m^2). The amount of CO_2 emission during building work was found to constitute about 85% of all emissions during the construction procedure. Table 3 shows the unit CO_2 emission and its percentage per construction process [14].

This study was limited to the process of building work because it was impossible to compare construction processes under identical conditions. The process of facility work varies according

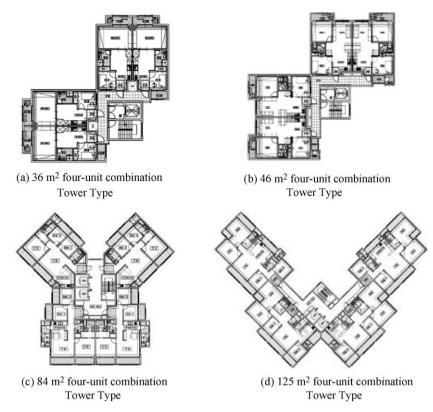

Fig. 2. Block arrangements and combinations of living units of general standard apartment houses.

 Table 2

 Constitution of super high-rise standard apartment houses.

Constitution	Description	
Lettable area	$118.00 \mathrm{m}^2$, $121.00 \mathrm{m}^2$, $178.00 \mathrm{m}^2$	
Block arrangement	Tower type: the ratio of the short side to the long side on a plan is 1:4 or less.	
Combination of living units	Tower type: 1 combination (single combination)	
Height of floor	2.9 m: air supply and ventilation systems are taken into account.	
Number of floors	60-story building	
Structure	Wall column structure of reinforced concrete	
Concrete strength	Structure	1st to 45th: 40 MPa 46th to 60th: 36 MPa
	Core	1st to 45th: 50 MPa 46th to 60th: 40 MPa

to the type and dimensions of a facility and the scope of the energy saving plan, while earth work also varies depending on work type and soil quality. Also, floors below ground level were excluded, because it was impossible to establish the same criteria for size and purpose for these floors [15].

Table 3 Unit CO₂ emissions and percentage per construction process.

Process	Unit CO ₂ emission (unit: kg-CO ₂ /m ²)	Percentage (%)
Building work	352.36	85.3
Facility work	49.68	12.0
Earth work	11.15	2.7
Total	413.19	100.0

3.2. Selection of main construction materials

Most of the current environmental load evaluation programs for buildings are operated by simply entering data on the specifications of material quantities after the detail design stage of a building. This method has shortcomings that are difficult to evaluate for an environmental load evaluation at the basic design stage, and significant time and effort are required to input all of the construction materials used.

To remedy such problems, those construction materials having considerable effects on the occurrence of environmental load, i.e., main materials, should be selected first.

In this study, the construction materials significantly contributing to CO_2 emissions were selected according to the unit CO_2 emissions. These emission levels were determined by an interindustry analysis on the development of technologies to reduce CO_2 emission based on the construction and material quantities for an apartment building. As for the process of building work, six main materials were selected for the general standard apartment houses: iron rods, REMICON (ready mixed concrete), plywood, concrete products, industrial plastic products, and paints. Seven main materials were selected for the super high-rise standard apartment house: iron rods, REMICON, plywood, concrete products, industrial plastic products, paints, and aluminum products. The ratios of CO_2 emission per material group are explained in Table 4.

4. Estimation of main construction material quantities and establishment of a unit materials database for standard apartment house

4.1. Estimation of quantities of main construction materials

To estimate the quantities of the main construction materials for the general standard apartment houses, the scope of estimation was limited to the six groups of main materials, with

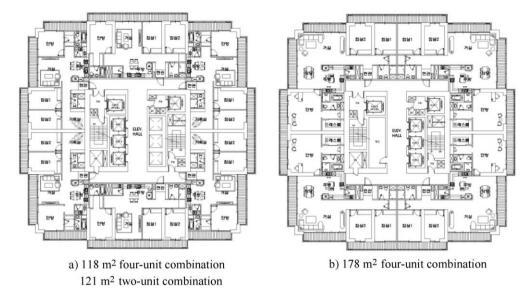

Fig. 3. Block arrangement and combination of living units of super high-rise standard apartment house.

Table 4Ratios of CO₂ emission per main material group.

Main material group	Amount of CO ₂ emission
Iron rods	42.37%
REMICON (ready mixed concrete)	23.72%
Plywood	4.03%
Concrete products	3.47%
Industrial plastic products	3.37%
Paints	3.13%
Aluminum products	6.17%
Total	86.26%

90 variables of estimation according to the combinations of five areas, three types of block arrangement, and six floors. For the super high-rise standard apartment house, the scope was limited to the seven groups of main materials for a 60-story building with a single type of block arrangement composed of three areas. Table 5 shows the scopes of quantity estimation per standard apartment house. Of the estimated main construction materials, the difference between the general and the super high-rise standard apartment houses is whether aluminum products were used in the doors and windows.

When the main material quantities were estimated per group, the main materials were selected, and then the itemized unit costs provided in the Standard Estimating System of the construction work were applied to the selected materials so that other submaterials were all estimated. The number of the estimated materials is 71.

Therefore, it was possible to determine the scope of estimation by selecting a combination of area, block arrangement, combination of living units, number of floors, and other alternative elements. Subsequently, a database was established for the estimation of quantities to be carried out automatically according to the decided scope. Tables 6 and 7 show the specifications of the estimated quantities per main material and of the estimated quantities by the itemized unit costs for the general standard apartment houses. Tables 8 and 9 shows these specifications of calculated material quantities and on calculated basic unit for the super high-rise standard apartment house.

4.2. Establishment of a database for the basic units of main materials

The methods to analyze basic units of construction materials are divided largely into an individual integration method, including inter-industry analysis and a mixed analysis. The individual integration method is an attempt to identify and integrate the environmental loads during such stages of a building life cycle as collection, transportation, and processing of construction materials and energy. Inter-industry analysis is a method by which an analysis is made through direct/indirect relations in the flows of construction materials and energies, based on the circulation data of construction materials and the energies used during the life cycle of a building. The inter-industry analysis is provided in the Input–Output Table by the Bank of Korea. The mixed analysis is a combination of the individual integration method and the inter-industry analysis so as to compensate for the weak points of each method [16–18].

As shown in Table 10, a database on the basic units of the main materials was established by mixed analysis including 94 construction materials classified by a national LCI database according to the individual integration method and basic units

of materials according to the inter-city analysis on the basis of the Input-Output Table for the year 2003 [19].

Using the established database on the basic units of the main materials according to the mixed analysis, data can be input into the basic design stage according to a selected combination of area, block arrangement, combination of living units, number of floors, and other alternative elements. Through an automatic estimation of quantities, the amount of CO_2 emitted by the main materials to be used for a construction project can be calculated as shown in the following Eq. (1):

The amount of CO₂ emission by the main materials

$$= \sum (Quantity \ of \ a \ main \ material \times Basic \ unit \ of \ CO_2) \eqno(1)$$

5. A case of environmental load evaluation

5.1. Overview

The construction conditions of a general standard apartment house were based on those of an existing apartment house built in

May 2004. For the existing apartment house, the environmental load (CO_2) was calculated with the Input–Output Table (2003, Domestic and Overseas) using the data from the total volume of the materials used in the construction work. Also, the environmental load for the general standard apartment house was calculated with the Input–Output Table used in estimating the environmental load for the existing apartment house using main material quantities, which were drawn from the method presented by this study. Then, the results of environmental load were comparatively analyzed [20].

5.2. Conditions of environmental load evaluation

The existing apartment house was a 20-story building with 40 households, the areas of which were 85.65 m². The general standard apartment house in this study was designed to have the same conditions of evaluation as a 20-story building with 40 households, each with an area of 84.0 m². The constructions of the existing and general standard apartment houses are summarized in Table 11.

5.3. Method of environmental load evaluation

The environmental load for the existing apartment house was evaluated based on the specifications of material quantities made after construction according to the Input–Output Table, and that of the general standard apartment house was evaluated through an automatic estimation of quantities of the main materials according to the mixed analysis. The former method and the method suggested by this study are compared in Table 12.

5.4. Results of environmental load evaluation

As a result of the environmental load evaluation, the load for the general standard apartment house suggested by this study was evaluated to be 1554.00 ton-CO₂, about 77.5% (2005.75 ton-CO₂) of

Comparison of the methods used to evaluate apartment houses.

Item	Former method	Method suggested by the study
Stage of evaluation	After construction	Stage of basic design
Quantity of material	Actual amounts of the materials used	Direct calculation of the materials
How to input	Direct entering of data of material quantities	Automatic calculation of quantities of materials
Method of evaluation	Inter-industry analysis	Mixed analysis

Table 13Results of environmental load evaluation.

Evaluation item	Existing apartment house (ton-CO ₂)	Standard apartment house (ton-CO ₂)
Amount of environmental load	2005.75	1554.00
Ratio of environmental load	100%	77.48%

that calculated with the material data used in building the existing apartment house. To estimate the amount of CO_2 emitted by the construction materials for the suggested general standard apartment house, this study chose a method for selecting main construction materials that emit about 80% of the CO_2 emitted from the production of materials used for building an apartment house.

Therefore, it is thought that the method in this study is useful to evaluate environmental load for the process of producing construction materials by selecting main materials for the suggested standard apartment house. Because the result of our method is close to the initial target, 80% of the $\rm CO_2$ emission from the materials used in a general apartment house, it will be possible to estimate the total amount of $\rm CO_2$ emissions based on the construction materials used in the building of an apartment house. Table 13 shows the results of environmental load evaluation.

6. Conclusions

This study aimed to develop a technique for evaluating the environmental load (CO_2) of an apartment house with data available in the planning and basic design stages. The results of the study are as follows:

- 1. The models of a general standard apartment house and of a super high-rise standard apartment house were selected based on the five floor plans designated by the Green Home evaluation reference houses of the government.
- 2. Main construction materials contributing to more than about 80% of the CO₂ emission in building work were selected, and the quantities of the main materials were calculated according to the type of apartment houses. Using the quantity data, a database was established to evaluate environmental load.
- 3. The environmental load from the production of construction materials in the building of the general standard apartment house suggested by this study was evaluated to be 1554.00 Ton-CO₂, about 77.5% of that emitted from an existing apartment house and close to the initial target of 80%.
- 4. Therefore, it is believed that the proposed method will be allow the evaluation, at the stages of architectural planning and basic design, of the amount of CO₂ to be emitted by the production of construction materials in a building project using such data as

- area, block arrangement, combination of living units, and number of floors.
- 5. In addition, the results of this study are considered to be useful as basic data for developing, in the stage of basic design, a program to evaluate the environmental load for the entire life of a building, without using any data obtained during the construction stage.
